## ABSTRACT

Hydroxylamine nitrate (HAN)-based electrically controlled solid propellants are currently the mainstream electrically controlled solid propellants. To gain a deeper understanding of their electrically controlled combustion mechanisms, this study employed quantum chemical simulations to systematically explore the electrocatalytic decomposition of HAN on a Cu(111) surface. The findings indicate that the electrocatalytic decomposition of  $\text{NO}_3^-$  ions on the anode surface is the dominant reaction for  $\text{O}_2$  generation, with a reaction barrier significantly lower than that of water electrolysis, demonstrating a pronounced reaction advantage. By optimizing the configurations of adsorbed molecules during the reaction and calculating the barriers for each reaction step, we have detailed the mechanism of HAN's electrocatalytic decomposition on the Cu(111) surface. Additionally, the reaction on a cathode surface is relatively facile, with the key step being the adsorption and decomposition of  $\text{NH}_3\text{OH}^+$  ions on the cathode surface. The generation of hydrogen ions in the anode reaction and their consumption in the cathode reaction lead to the cathode solution becoming alkaline and the anode solution becoming acidic after electrolysis. These findings provide important theoretical insights into the electrically controlled combustion mechanisms of HAN-based electrically controlled solid propellants.

## 1. Introduction

Electrically controlled solid propellants, a new variant that can be ignited, burned, and extinguished using electrical energy control, are attracting widespread attention in the controllable propulsion field [1]. At present, most electrically controlled solid propellants are based on hydroxylamine nitrate (HAN) [2], a high-energy oxidant with a high specific impulse and low toxicity [3].

Research on HAN has mainly focused on the mechanism of thermal decomposition. In separate studies using mass spectrometry, Izato *et al.* [4] and Souagh *et al.* [5] commonly identified  $\text{HNO}_3$ ,  $\text{N}_2\text{O}$ , and  $\text{H}_2\text{O}$  as thermal decomposition partial products of HAN, but Izato *et al.* [4] believed that the products also include  $\text{N}_2$  and  $\text{NH}_3$ , and Souagh *et al.* [5] considered the products also include  $\text{NO}$  and  $\text{NO}_2$ . Using an infrared spectrometer, Cheng *et al.* [6] identified  $\text{N}_2\text{O}$ ,  $\text{NO}$ ,  $\text{H}_2\text{O}$ , and  $\text{NO}_2$  as the thermal decomposition products of HAN. Meanwhile, the reaction pathway of HAN thermal decomposition has been investigated through quantum chemical simulations. Early studies reported various formation pathways of  $\text{N}_2\text{O}$ . For example, Oxley *et al.* [7] believed that  $\text{N}_2\text{O}$  is produced by the reaction of intermediate products  $\text{HNO}_2$  and  $\text{NH}_2\text{OH}$ . In recent years, Izato *et al.* [4], Taylor *et al.* [8], and Zhang *et al.* [9] discovered that  $\text{N}_2\text{O}$  is produced by the reaction of intermediate products  $\text{HNO}$  and  $\text{HNO}$ . However, elucidating the electrocatalytic decomposition mechanism of HAN on electrode surfaces is essential for advancing the electrically controlled combustion mechanism of solid propellants. At present, this topic has been scantily researched

and usually focuses on electrolytic effects or product analysis. For example, Koh *et al.* [10] studied the effects of power supply and electrode materials on the electrocatalytic decomposition of HAN. They demonstrated higher performance with copper or aluminum electrodes than with carbon electrodes and reported that a power supply exceeding 100 W can effectively trigger decomposition. Sun *et al.* [11] studied the effects of electrolysis voltage and electrode surface area on the electrolysis of HAN solution. They reported an optimal voltage for electrolysis under fixed conditions. This is caused by an inhibition phenomenon at the anode, which can be alleviated by increasing the surface area of the anode electrode. Haung *et al.* [12] experimentally studied electrolysis in the HAN solution using a U-shaped bottle as the electrolytic cell container, which effectively separates the products of anode and cathode electrolysis. After electrolysis, the cathode and anode solutions became alkaline and acidic, respectively, producing  $\text{NH}_3$  on the cathode and  $\text{O}_2$  on the anode. Other scholars have studied the catalytic decomposition mechanisms of nitrate on electrode surfaces through quantum chemical simulations, providing useful references for studying the electrocatalytic decomposition mechanism of HAN on electrode surfaces. For example, Zhou *et al.* [13] studied the catalytic decomposition mechanism of HAN on electrode surfaces in depth. They optimized the adsorption configuration and catalytic decomposition pathway of HAN on Ir(110) surfaces. Calle-Vallejo *et al.* [14] calculated the variation trend of adsorption energy of nitrate on 20 surfaces of an Ag/Au bimetallic system. They showed that defective Ag/Au surfaces can enhance the catalytic activity of nitrate

reduction. Several researchers have also conducted computational studies on the electrocatalytic decomposition of water using quantum chemical simulations, which offer valuable insights. For instance, Ren *et al.* [15] analyzed the hydrogen evolution performance of a novel electrocatalyst, FeCoCuSx/CFF. Their results indicated that the Gibbs free energy of hydrogen adsorption at the Co sites within the CuS-Co9S8 heterostructure is close to zero. This finding suggests that the catalyst exhibits excellent hydrogen evolution performance.

To further elucidate the electrocatalytic decomposition mechanism of HAN on the electrode surface and explain the relevant experimental phenomena, this study builds upon the electrolysis experiments of HAN solution in a U-tube reported by Huang *et al.* [12]. We aim to explore the reaction pathways for the generation of  $\text{NH}_3$  and  $\text{O}_2$  during the electrocatalytic decomposition of HAN on the Cu (111) surface using quantum chemical simulations.

## 2. Materials and Methods

Small-molecule calculations were performed using the Gaussian 16 software [16]. The geometric optimization and vibration analysis of some small molecules were calculated using the B3LYP functional at the 6-31G(d) basis-set level. The B3LYP functional is commonly used and provides fast convergence with low dependence on integration lattice points. At the 6-31G(d) basis-set level, the B3LYP functional is sufficiently accurate for geometric optimization and vibration analysis [17]. The free energies of some small molecules were calculated using the coupled-cluster method with single, double, and perturbative triple excitations (CCSD(T)) method at the def2-QZVPP basis-set level. The CCSD (T) method is a high-precision quantum chemistry calculation method with sufficient accuracy at the def2-QZVPP basis-set level [18,19]. In this article, the adsorption structure of molecules on the Cu(111) surface was simulated using the CP2K software [20], which quickly calculates the periodic crystal structure of Cu metal using the density functional theory. Figure 1 is a unit cell model diagram of the Cu(111) surface, a common stable crystal plane. Panels (a) and (b) of this figure present a front and top view of the model, respectively. The adsorption structure was calculated under the Perdew–Burke–Ernzerhof functional with the DZVP–GTH pseudopotential basis set. The calculation speed was improved using the Gaussian plane wave method. The vacuum layer was set to 15 Å to avoid interactions between adjacent unit cell molecules, the plane wave cutoff energy was 600 Ry, the energy and intermolecular force convergence standards were set to  $10^{-6}$  Hartree and  $4.5 \times 10^{-4}$  Hartree/Bohr, respectively, and the k-point setting was  $3 \times 3 \times 1$ . The Van der Waals correction was performed using the Grimme method [21]. The free energy was calculated as

$$\Delta G = \Delta E + \Delta \text{ZPE} + \Delta H_{0 \rightarrow T} - T\Delta S,$$

where  $\Delta E$  and  $\Delta \text{ZPE}$  represent the changes in the single-point and zero-point energies, respectively,  $\Delta H_{0 \rightarrow T}$  represents the enthalpy change during a temperature change from 0 K to T, and  $\Delta S$  represents the entropy change.

### 2.1. Reaction path of electrocatalytic decomposition

Under water-solvent conditions, HAN decomposes into  $\text{NH}_3\text{OH}^+$  and  $\text{NO}_3^-$  ions [22]. The aqueous solvent condition is simulated using the implicit solvent SMD (Solvent Model based on Density) model. The configuration changes of HAN under vacuum and water-solvent

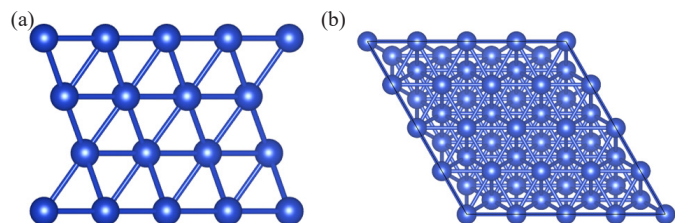

Figure 1. Unit cell model diagram of the Cu (111) surface: (a) front view; (b) top view.

conditions have been shown in Figure 2, and the energies were calculated using Gaussian 16 software [16]. Under vacuum and water-solvent conditions, the HAN molecule is configured as  $\text{NH}_2\text{OH} \cdot \text{HNO}_3$  and  $\text{NH}_3\text{OH}^+ \cdot \text{NO}_3^-$ , respectively. As  $\text{NH}_3\text{OH}^+ \cdot \text{NO}_3^-$  has a lower free energy of configuration than  $\text{NH}_2\text{OH} \cdot \text{HNO}_3$ , HAN easily decomposes into  $\text{NH}_3\text{OH}^+$  and  $\text{NO}_3^-$  ions under water-solvent conditions. The electrocatalytic decomposition mechanism of HAN has been shown in Figure 3, where ‘\*’ represents adsorbed molecules, and radicals are identified with ‘·’ (for example, ‘·OH’ denotes OH radicals). Under a potential difference, anions and cations will move toward the anode (which tends to lose electrons) and cathode (which tends to gain electrons), respectively. As the  $\text{NO}_3^-$  ions move toward the anode, they lose one electron and adsorb as  $^*\text{NO}_3$  on the anode surface Eq. (1). Figure 4(a) shows the configuration of  $^*\text{NO}_3$ . The two O atoms of  $\text{NO}_3$  are adsorbed on adjacent Cu atoms at the anode surface with different bond lengths (2.040 Å and 2.045 Å) and a bond angle of  $119.337^\circ$  between the adsorbed O and N atoms.  $^*\text{NO}_3$  dissociates into  $^*\text{NO}_2$  and  $^*\text{O}$  on the anode surface Eq. (2).  $^*\text{NO}_2$  is configured as shown in Figure 4(b). The two O atoms of  $\text{NO}_2$  are adsorbed on adjacent Cu atoms on the anode surface with the same bond lengths as  $^*\text{NO}_3$  (2.040 Å and 2.045 Å). The bond angle between the adsorbed O and N atoms is slightly smaller in  $^*\text{NO}_2$  than the bond angle between the adsorbed O and N atoms in  $^*\text{NO}_3$ . Figure 4(c) shows the configuration of  $^*\text{O}$ . The bond

lengths between the O and adjacent Cu atoms on the anode surface are 1.906 Å and 1.907 Å, with a bond angle of 88.604°.  $^*\text{NO}_2$  can desorb from the anode surface as  $\text{NO}_2$  see Eq. (3):

$\text{H}_2\text{O}$  molecules lose one electron, decomposing into  $^*\text{OH}$  and  $\text{H}^+$  ions on the anode surface Eq. (4). Figure 4(d) shows the configuration of  $^*\text{OH}$ . The bond lengths between the O atom and adjacent Cu atoms on the anode surface are 2.027 Å and 2.032 Å, with a bond angle of 84.646°.  $^*\text{OH}$  loses one electron on the anode surface, forming  $^*\text{O}$  and  $\text{H}^+$  Eq. (5). The  $^*\text{O}$  radicals react with  $\text{H}_2\text{O}$  molecules, losing one electron to form  $\text{H}^+$  and  $^*\text{OOH}$  Eq. (6). Figure 4(e) shows the configuration of  $^*\text{OOH}$ . The two O atoms of  $\cdot\text{OOH}$  are adsorbed on adjacent Cu atoms on the anode surface with bond lengths of 2.189 Å and 2.033 Å and bond angles of 89.832° and 109.330°, respectively.  $^*\text{OOH}$  loses one electron on the anode surface, forming  $\text{H}^+$  and  $\text{O}_2$  Eq. (7). The reaction equations are as follows:

Under the action of the potential difference,  $\text{NH}_3\text{OH}^+$  ions move toward the cathode, where they dissociate into  $^*\text{NH}_2\text{OH}$  and  $\text{H}^+$  ions on the cathode surface Eq. (8). Figure 4(f) shows the configuration of  $^*\text{NH}_2\text{OH}$ . The N atom of  $\text{NH}_2\text{OH}$  adsorbs with a bond length of 2.159 Å near the Cu atom on the cathode surface. The bond angles are 107.311° between the Cu, N, and H atoms and 113.946° between the Cu, N, and O atoms.  $^*\text{NH}_2\text{OH}$  dissociates into  $^*(\text{NH}_2 + \cdot\text{OH})$  Eq. (9) with the configuration shown in Figure 4(g). The bond lengths between the N atom of  $\cdot\text{NH}_2$  and the two adjacent Cu atoms on the cathode surface are 2.000 Å and 1.994 Å with a bond angle of 113.946°. Meanwhile, the bond lengths between the O atom of  $\cdot\text{OH}$  and the two adjacent Cu atoms on the cathode surface are 2.042 Å and 2.024 Å, with a bond angle of 83.845°.  $^*\text{NH}_2$  obtains an electron at the cathode and

combines with  $\text{H}^+$  ions to form  $\text{NH}_3$  Eq. (10). Figure 4(h) shows the configuration of  $\text{NH}_2$ . The N atom of  $\cdot\text{NH}_2$  bonds with two adjacent Cu atoms on the cathode surface with bond lengths of 1.990 Å and 1.991 Å and a bond angle of 82.757°.  $^*\text{OH}$  obtains an electron at the cathode and combines with  $\text{H}^+$  ions to form  $\text{H}_2\text{O}$  Eq. (11). The reaction equations are as follows:

### 3. Results and Discussion

#### 3.1. Anodic reaction mechanism

Table 1 lists the thermodynamic parameters of the relevant molecules during the anodic reaction process, calculated using CP2K software. As analyzed in the previous section,  $\text{NO}_3^-$  ions near the anode first lose one electron and adsorb to the anode surface. To avoid the CP2K calculation of the free energy of  $\text{NO}_3^-$  ions, the formation free energy of Eq. (1) was obtained by summing the formation free energies of Eqs. (12), (13), and (14); that is,  $\Delta G_1 = \Delta G_{12} + \Delta G_{13} + \Delta G_{14}$ , where  $\Delta G$  represents the formation free energy and the subscript denotes the number of the reaction equation. In this expression,  $\Delta G_{12} = G(^*\text{NO}_3) + 0.5G(\text{H}_2(\text{g})) - G(\text{HNO}_3(\text{g})) - G(^*)$ , where  $G$  represents the free energy and  $\text{H}^+ + e^-$  is replaced by half the free energy of  $\text{H}_2$ . According to Calle-Vallejo *et al.* [14],  $\Delta G_{13} = 0.317$  eV and  $\Delta G_{14} = 0.075$  eV. As only the vibrations of adsorbed molecules are relevant, the surface free energy of the anode is replaced by the single-point energy [23]. From the data in Table 1,  $\Delta G_1$  was determined as 0.001 eV. Eqs. (12)–(14) are computed as

Note: \*: anodic surface; E<sub>ele</sub>: Single-point energy; T: Temperature; ZPE: Zero-point energy; ΔG: Free energy correction; G: Represents free energy.

The formation free energy of \*NO<sub>3</sub> dissociation into \*NO<sub>2</sub> and \*·O on the anode surface can be expressed as  $\Delta G_2 = G(*NO_2) + G(*·O) - G(*NO_3) - G(*)$ . From the data in Table 1,  $\Delta G_2$  was obtained as -0.811 eV. Given the formation free energy of NO<sub>2</sub> on the anode surface  $\Delta G_3 = G(*) + G(NO_2(g)) - G(*NO_2)$  and the data in Table 1,  $\Delta G_3$  was obtained as 1.125 eV. The formation free energy of H<sub>2</sub>O molecules decomposing into \*·OH and H<sup>+</sup> ions on the anode surface can be expressed as  $\Delta G_4 = G(*·OH) + 0.5G(H_2(g)) - G(H_2O(l)) - G(*)$ , giving  $\Delta G_4 = 0.310$  eV based on the data in Table 1. The free energy of \*·O and H<sup>+</sup> formation on the anode surface after \*·OH adsorption is computed as  $\Delta G_5 = G(*·O) + 0.5G(H_2(g)) - G(*·OH)$ , from which  $\Delta G_5 = 0.782$  eV from the data in Table 1. The formation free energy of H<sup>+</sup> and \*·OOH formed by the reaction between \*·O and H<sub>2</sub>O molecules is  $\Delta G_6 = G(*·OOH) + 0.5G(H_2(g)) - G(*·O) - G(H_2O(l))$ . From the data in Table 1,  $\Delta G_6$  was obtained as 2.799 eV. Finally, the formation free energy of H<sup>+</sup> and O<sub>2</sub> on the anode surface of \*·OOH, given by  $\Delta G_7 = G(*) + G(O_2(g)) + 0.5G(H_2(g)) - G(*·O) - G(H_2O(l))$ , was obtained as  $\Delta G_7 = 1.028$  eV using the data of Table 1.

From the above analysis, it was concluded that O<sub>2</sub> on the anode surface can be formed through two pathways: electrocatalytic decomposition of NO<sub>3</sub><sup>-</sup> ions and electrocatalytic decomposition of H<sub>2</sub>O molecules. Figure 5 shows the potential barrier diagram of NO<sub>3</sub><sup>-</sup> ion decomposition on the anode surface. The potential barrier of electron adsorption of NO<sub>3</sub><sup>-</sup> ions is almost 0, and that of \*NO<sub>3</sub> decomposition into \*NO<sub>2</sub> and \*·O is negative, indicating that the process can easily spontaneously occur. Meanwhile, NO<sub>2</sub> desorption, \*·O to \*·OOH conversion, and \*·OOH to O<sub>2</sub> conversion must cross potential barriers of 1.125, 2.799, and 1.028 eV, respectively. Figure 6 shows the potential barrier diagram of H<sub>2</sub>O decomposition on the anode surface. The conversion of adsorbed H<sub>2</sub>O molecules to \*·OH, conversion of \*·OH to

**Figure 5.** Reaction barrier diagram of NO<sub>3</sub><sup>-</sup> ion decomposition on the anode surface.**Figure 6.** Reaction barrier diagram of H<sub>2</sub>O molecule decomposition on the anode surface.

\*·O, and subsequent conversion to \*·OOH and O<sub>2</sub>, like NO<sub>3</sub><sup>-</sup> ions, must cross potential barriers of 0.310 eV, 0.782 eV. As NO<sub>3</sub><sup>-</sup> conversion to O<sub>2</sub> has a lower potential barrier than H<sub>2</sub>O conversion to O<sub>2</sub> on the anode surface, the decomposition rate of NO<sub>3</sub><sup>-</sup> exceeds that of H<sub>2</sub>O, and NO<sub>3</sub><sup>-</sup> decomposition is the main pathway of O<sub>2</sub> generation at the anode.

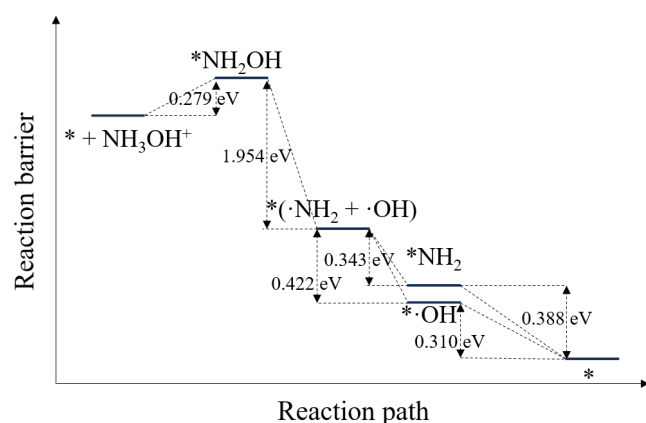

### 3.2. Cathodic reaction mechanism

Table 2 lists the thermodynamic parameters of the molecules involved in the cathodic reaction process, calculated using CP2K software. As analyzed in the previous subsection, NH<sub>3</sub>OH<sup>+</sup> ions first dissociate into \*NH<sub>2</sub>OH and H<sup>+</sup> ions on the cathode surface. To avoid the CP2K calculation of the free energy of NH<sub>3</sub>OH<sup>+</sup> ions, the formation free energy of the acid-dissociation reaction of NH<sub>3</sub>OH<sup>+</sup> ions Eq. (15) was first calculated using Gaussian software. Next, the formation free energy of Eq. (16) was calculated in CP2K software to obtain the formation free energy of Eq. (8), namely,  $\Delta G_8 = \Delta G_{15} + \Delta G_{16}$ , where the formation free energy of Eq. (15) was calculated as  $\Delta G_{15} = 0.349$  eV and that of Eq. (16) was obtained as  $\Delta G_{16} = G(*NH_2OH) - G(NH_2OH) - G(*) = 0.310$  eV using the data in Table 2. Therefore,  $G_8$  was obtained as 0.279 eV. The formation free energy of NH<sub>2</sub>OH dissociation into \*(·NH<sub>2</sub> + ·OH) is  $\Delta G_9 = G(*(\cdot NH_2 + \cdot OH)) - G(*NH_2OH)$ . From the data in Table 2,  $\Delta G_9$  was obtained as -1.954 eV. The reaction equations are given by

**Table 2.** Thermodynamic parameters of the molecules involved in the cathodic reaction process.

**Figure 7.** Reaction barrier diagram of  $\text{NH}_3\text{OH}^+$  ion decomposition on the cathode surface.

$\cdot(\text{NH}_2 + \cdot\text{OH})$  reacts with  $\text{H}^+$  ions to remove an  $\text{H}_2\text{O}$  molecule Eq. (17). Next,  $\cdot\text{NH}_2$  and  $\text{H}^+$  ions combine to form  $\text{NH}_3$  Eq. (17) with a formation free energy of  $\Delta G_{17} = G(\cdot\text{NH}_2) + G(\text{H}_2\text{O}(\text{l})) - G(\cdot(\text{NH}_2 + \cdot\text{OH})) - 0.5G(\text{H}_2(\text{g}))$ . From the data in Table 2,  $\Delta G_{17}$  was obtained as  $-0.343$  eV. Meanwhile, the formation free energy of Eq. (10) is  $\Delta G_{10} = G(\cdot) + G(\text{NH}_3) - G(\cdot\text{NH}_2) - 0.5G(\text{H}_2(\text{g})) = -0.388$  eV using the data in Table 2.  $\cdot(\text{NH}_2 + \cdot\text{OH})$  reacts with  $\text{H}^+$  ions to remove an  $\text{NH}_3$  molecule Eq. (18). The  $\cdot\text{OH}$  and  $\text{H}^+$  ions then combine to form  $\text{H}_2\text{O}$  with a formation free energy of  $\Delta G_{18} = G(\cdot\text{OH}) + G(\text{NH}_3) - G(\cdot(\text{NH}_2 + \cdot\text{OH})) - 0.5G(\text{H}_2(\text{g}))$ . From the data in Table 2,  $\Delta G_{18}$  was obtained as  $-0.422$  eV. The formation free energy of Eq. (11) is  $\Delta G_{11} = G(\cdot) + G(\text{H}_2\text{O}(\text{l})) - G(\cdot\text{OH}) - 0.5G(\text{H}_2(\text{g}))$ . From the data in Table 2,  $\Delta G_{11}$  was determined as  $-0.310$  eV. The reaction equations are as follows:

As shown in the above analysis,  $\text{NH}_3\text{OH}^+$  ions gradually decompose on the cathode surface. Figure 7 shows the reaction potential-barrier diagram of  $\text{NH}_3\text{OH}^+$  decomposition on the cathode surface. The potential barrier of electron adsorption by  $\text{NH}_3\text{OH}^+$  ions and subsequent  $\cdot\text{NH}_2\text{OH}$  decomposition is  $0.279$  eV. As the energy increases during conversion, the reaction cannot easily proceed spontaneously. However, when  $\cdot\text{NH}_2\text{OH}$  decomposes into  $\cdot(\text{NH}_2 + \cdot\text{OH})$ , the energy barrier is lowered and this reaction can spontaneously proceed. The energy also decreases when  $\cdot(\text{NH}_2 + \cdot\text{OH})$  converts to  $\cdot\text{NH}_2$  and  $\cdot\text{OH}$ , but the larger decrease in energy during conversion to  $\cdot\text{OH}$  than of conversion to  $\cdot\text{NH}_2$ . Finally, the desorption of adsorbed molecules  $\cdot\text{NH}_2$  and  $\cdot\text{OH}$  from the cathode surface can also spontaneously proceed. Therefore, the decisive step in  $\text{NH}_3\text{OH}^+$  decomposition is electron adsorption and decomposition of  $\text{NH}_3\text{OH}^+$  ions to  $\cdot\text{NH}_2\text{OH}$ . All subsequent decomposition processes can spontaneously occur.

#### 4. Conclusions

The main conclusions of the study are summarized below.

- (1) Under water-solvent conditions, HAN easily decomposes into  $\text{NH}_3\text{OH}^+$  and  $\text{NO}_3^-$  ions. Under the action of a potential difference,  $\text{NH}_3\text{OH}^+$  ions and  $\text{NO}_3^-$  ions move toward the cathode and anode, respectively, where they undergo electrocatalytic decomposition reactions. Specifically,  $\text{NH}_3\text{OH}^+$  ions decompose into  $\text{NH}_3$  and  $\text{H}_2\text{O}$  on the cathode surface, and  $\text{NO}_3^-$  ions decompose into  $\text{NO}_2$  and  $\text{O}_2$  on the anode surface.
- (2)  $\text{O}_2$  at the anode surface can be generated via two pathways: the electrocatalytic decomposition of  $\text{NO}_3^-$  ions and the electrocatalytic decomposition of  $\text{H}_2\text{O}$  molecules on the anode surface. The key difference between these two pathways lies in the formation of the

$\cdot\text{O}$  intermediate. For  $\text{NO}_3^-$  ions, the energy decreases during the formation of  $\cdot\text{O}$ , with a reaction barrier of  $-0.811$  eV, indicating that the reaction is highly spontaneous. In contrast, for  $\text{H}_2\text{O}$  molecules, the energy increases during the formation of  $\cdot\text{O}$ , with a reaction barrier of  $+0.782$  eV. This suggests that the formation of  $\cdot\text{O}$  from  $\text{H}_2\text{O}$  is more challenging. Therefore, the electrocatalytic decomposition of  $\text{NO}_3^-$  ions on the anode surface are the dominant pathway for  $\text{O}_2$  generation at the anode.

- (3) The cathodic surface reaction easily occurs, and its rate-determining step is the electron adsorption and decomposition of  $\text{NH}_3\text{OH}^+$  ions to form  $\cdot\text{NH}_2\text{OH}$ . The energies of all subsequent decomposition processes decrease, indicating that the reaction occurs spontaneously. On the cathodic surface,  $\cdot(\text{NH}_2 + \cdot\text{OH})$  conversion to  $\cdot\text{NH}_2$  competes with  $\cdot(\text{NH}_2 + \cdot\text{OH})$  conversion to  $\cdot\text{OH}$ . The greater energy decrease during conversion to  $\cdot\text{OH}$  indicates a higher reaction rate of  $\cdot\text{OH}$  formation than of  $\cdot\text{NH}_2$  formation from  $\cdot(\text{NH}_2 + \cdot\text{OH})$ .
- (4) During the anodic reaction, several processes generate hydrogen ions ( $\text{H}^+$ ), while at the cathode, multiple reactions consume hydrogen ions. This leads to the cathodic solution becoming alkaline and the anodic solution becoming acidic after the electrocatalytic decomposition of the HAN solution.
- (5) The electrocatalytic decomposition mechanism of HAN on the Cu(111) surface is highly complex. This study primarily analyzes the main pathways for the formation of  $\text{O}_2$  and  $\text{NH}_3$ . Future research could utilize quantum chemical simulations to predict potential by-products, thereby guiding experimental investigations. Additionally, deeper insights into the reaction mechanism could be revealed through atomic charge calculations and orbital composition analysis.
